# Abstract

Integrated plasmonics is advancing rapidly, enabling a wide range of functionalities to be incorporated onto a single chip. Applications span information processing, computation, quantum sensing, and dark-matter detection. This progress has driven the development of integrated non-reciprocal devices, which are essential for preventing unwanted feedback that can degrade system performance. While non-reciprocal devices have been realized in edge magnetoplasmon materials via classical interference effects, their operation is often complicated by a dependence on input power. Here, we demonstrate that topological circulators utilizing asymmetric coupling offer improved input power range, isolation, and insertion loss. In this configuration, non-reciprocal behavior arises from the coupling between a chiral edge magnetoplasmonic resonator and LC resonators, leading to non-Hermitian dynamics. The coherent photon-plasmon interaction enables a circulator with up to 50 dB of isolation across a broad range of excitation intensities. This is the first experimental demonstration showing that magnetic topological insulators can support the study of chiral plasmonic cavity quantum electrodynamics at radio frequencies, underscoring their potential to enable chip-scale quantum-classical interfaces in superconducting quantum information processing systems.

Keywords: Non-reciprocal devices, Topological Insulator, Cavity Quantum Electrodynamics

# I. INTRODUCTION

The chiral, dissipationless nature of the edge magnetoplasmon makes it a promising candidate for advancing chip-scale non-reciprocal devices at quantum-classical interfaces [1– 3]. Although the propagation of edge magnetoplasmons (EMPs) has been extensively studied in quantum Hall (QH) systems [4–6], their coupling to an external device within the regime of cavity quantum electrodynamics (cQED) remains largely unexplored. It has recently been pointed out that the QH edge magnetoplasmon state could be valuable for measuring and controlling solid-state qubits, due to its inherently high characteristic impedance, quantized as  $h/\nu e^2$  with  $\nu$  the Landau-level filling factor[7, 8]. As a result, high-impedance plasmonic transmission lines and resonators are predicted to achieve strong coupling to external twolevel systems, such as spin qubits, thereby enabling exploration of plasmonic cavity quantum electrodynamics [7, 9, 10]. Compared to quantum Hall systems, quantum anomalous Hall (QAH) materials offer distinct advantages, such as maintaining a stable number of edge channels across a broad range of applied magnetic fields, including in the absence of a magnetic field [11, 12]. This makes them well-suited for integration with both superconducting circuits and semiconductor devices. The QAH insulator, Cr-doped  $(\text{Bi}_x \text{Sb}_{1-x})_2 \text{Te}_3$ , provides a promising platform for realizing strong plasmon-photon interactions. This is due to its high-impedance plasmon mode, with an impedance of  $Z = h/Ce^2 \sim 25.8 \text{ k}\Omega$  and a Chern number C = 1. Because the zero-point voltage fluctuation scales as  $\sqrt{Z}$ , this large Z markedly amplifies the electric-dipole coupling between the plasmon and nearby quantum emitters, making highimpedance edge magnetoplasmonic resonators ideal for achieving strong plasmon-photon coupling, opening up exciting opportunities in electronic quantum optics.

In this work, we investigate a coupled plasmon-photon system, in which an on-chip QAH plasmon resonator is asymmetrically coupled to a pair of LC resonators. The hybrid system exhibits a pronounced transmission minimum superimposed on the LC resonant peak along one path, while exhibiting high transmission along the other path. This circulation behavior arises from the Hatano-Nelson type coupling [13–15] between the chiral edge magnetoplasmon resonator and the LC resonators. Moreover, we demonstrate that the plasmon-photon interaction achieves an average isolation of 20 dB across approximately 50 MHz of bandwidth near the resonant frequencies, even with an input microwave power as low as -149 dBm. These findings establish a novel mechanism for exploiting the intrinsic unidirectionality of QAH edge states in the engineering of non-reciprocal devices, with promising implications for scaling up superconducting quantum processors and axion haloscopes.

# II. RESULTS

#### A. Experimental setup.

The configuration of our three-port circulator device is shown in the lower right corner of Fig. 1, and consists of an EMP resonator with a radius of 100  $\mu$ m and three lumped element inductors, each with an inductance L = 180 nH. The inductor and the stray capacitor  $C_{\text{stray}}$  form an LC resonator, whose resonance frequency  $\omega_{LC} = 1/\sqrt{LC_{\text{stray}}}$  is set to closely match the EMP resonance frequency  $\omega_m$ . At each port of the circulator, the EMP resonator is

Components *a* and *b* (blue pads) represent the LC resonator at ports 1 and port 3, respectively.  $m_1$  and  $m_2$  represent the transport of the EMPs from resonator *a* to *b*, and from *b* to *a*, respectively. c, Schematic of the circulator. Three 180 nH lumped-element wire-loop inductors are wire-bonded adjacent to the QAH mesa. d, Schematic of the three-port circulator device, consisting of a QAH mesa with an edge conductance of  $e^2/h$ , and three inductors positioned between the mesa and the transmission line of the printed circuit board. Edge magnetoplasmon resonant modes are excited and propagate dissipationlessly along the edge of the circular mesa.

capacitively coupled to an LC resonator through an edge capacitor  $C_{\text{edge}}$ , which is formed between the Au pad and the EMP resonator (Fig. 1b). The microwave transmission coefficients  $S_{31}$  and  $S_{32}$  are characterized using a measurement scheme depicted in Fig. 1a and described in Appendices A and B. All measurements were performed at a temperature of approximately 10 mK.

#### B. Circulator Characterization.

The primary result of this work is the non-reciprocal response of the device, including the transmission contrast and the phase shift when excited from different ports, thus producing circulation. Figures 2 a and b show forward transmission for the two paths  $S_{31}$  and  $S_{32}$  as a function of frequency. The response is clearly non-reciprocal  $S_{31} \neq S_{32}$  in amplitude  $|S_{i,j}|$  and

phase  $\phi_{i,j}$ . A particularly interesting response arises for f = 543.8 MHz, where the amplitude difference between  $|S_{31}|$  and  $|S_{32}|$  exceeds 50 dB, and  $S_{31}$  undergoes an abrupt phase shift of approximately 180° relative to  $S_{32}$  (see Appendix C for details). This pronounced nonreciprocal transmission, accompanied by a corresponding  $\pi$ -phase shift, indicates proximity to an exceptional point, where the coupling between the pair of LC resonators vanishes in one direction. [16–18].

A positive phase variation results in a negative group delay, expressed as  $\tau_G = -\delta \phi / \delta \omega$ . This characteristic can be utilized in devices such as temporal circulators or gyrators, which allow the separation of transmitter and receiver signals in the time domain through a directional  $\pi$ -phase shift. Such non-reciprocal phase shifts are critical for applications requiring signal isolation and directional wave control. We demonstrate the effect of negative group delay by calculating the time-domain response to a simulated narrow-band incident pulse injected at port 1, with a center frequency of 543.8 MHz and a 50-Hz bandwidth, as shown in Fig. 2c. The output pulse leaving port 3 is computed by convolving the simulated incident pulse and the experimentally obtained transmission spectrum. Figure 2d shows the calculated output wave, where the peak of the envelope arrives approximately 3.36  $\mu$ s earlier than the incident wave, indicating a negative group delay. While positive group delays are common, negative group delays-often associated with superluminal effects-are rare and typically emerge in exotic physical systems [19–22]. The port-dependent group delay, combined with the transmission amplitude demonstrated here, could be exploited in the development of novel on-chip components, such as isolators and circulators based on directional phase engineering. The underlying physical mechanism responsible for the observed negative group delay will be discussed in the Simulation section.

Next, we examine the transmission in an EMP resonator, both with and without LC resonators, across a wide spectral range. The transmission through the same EMP resonator, without coupling to an LC resonator, is shown in Figs. 3 a–c. Due to the constructive and destructive interference between the EMP mode and the port-to-port RF signal transmitted through the parasitic capacitance  $C_p$  (Fig. 1),  $S_{31}$  and  $S_{32}$  exhibit a non-reciprocal response with a bandwidth of approximately 100 MHz. The isolation magnitude,  $|S_{32}| - |S_{31}|$ , reaches a maximum of 20 dB over a circulation intensity range of approximately 5 dBm. Figures. 3 d–f show the transmission spectra as a function of frequency and input power when the EMP and LC resonators are coupled. For excitation from port 1, the magnitude of  $S_{31}$ 

Figure 2. Circulator transmission measurement. a, b, Experimental results for the transmission magnitude and phase an input power of -120 dBm, corresponding to the RF power estimated at the input ports of the circulator. Measurements were made in a dilution refrigerator maintained below 10 mK. The  $S_{31}$  and  $S_{32}$  magnitudes have been normalized such that the maximum of  $S_{32}$  is unity. c, d, The calculated time-domain response of the circulator to incident waves with a center frequency of 543.8 MHz and a 50 Hz bandwidth. The output wave indicates a negative group delay of approximately  $-3.36 \ \mu$ s.

is smaller than -15 dB if the input power is smaller than -130 dBm. In contrast, for excitation from port 2, the magnitude of  $S_{32}$  remains nearly unchanged over an input power range larger than 50 dBm. The device exhibits non-reciprocity of ~ 20 dB over the input intensity range from -150 to -90 dBm (Fig. 3f), which is relevant for several applications, including superconducting quantum information science[23] and dark-matter axion searches [24].

The spectral response at varying input power levels is presented in greater detail in Figs. 3 g-i. At an input power of P = -149 dBm at the circulator's port,  $S_{32}$  exhibits a Lorentzianlike resonance with the quality factor Q = 236, while  $S_{31}$  shows a subtle resonance peak (Fig. 3g). Compared to the EMP circulator without coupling to an LC resonator, the LCresonator-coupled configuration achieves significantly higher transmission, with an insertion loss of approximately 6 dB at the transmission peak (see Appendix D). This enhancement can be attributed to the impedance matching between the port impedance and the impedance of the QAH edge state. Transmission can be enhanced to near-unity levels through optimized impedance matching and improved circuit fabrication.

The broadband non-reciprocal response in the 450–650 MHz frequency range of the LCresonator-coupled EMP circulator arises from the interference between phase-sensitive plasmonic and parasitic capacitance pathways. For the shorter edge path (port 2 to 3), two LC resonators are capacitively coupled to the EMP resonator, leading to constructive in-

Figure 3. Transmission response for circulators with and without coupling to an LC resonator. a–c, Microwave transmission response  $|S_{31}|$ ,  $|S_{32}|$ , and  $|S_{32}| - |S_{31}|$  for a 100  $\mu$ m-radius circulator with increasing port input power. The signal is excited from ports 1 and 2, and measured at port 3.  $|S_{31}|$  and  $|S_{32}|$  curves are normalized for clarity.  $|S_{31}| - |S_{32}|$  is shown without normalization. d–f, Transmission response  $|S_{31}|$ ,  $|S_{32}|$ , and  $|S_{32}| - |S_{31}|$  for a 100  $\mu$ m-radius circulator coupled to LC resonators.  $|S_{31}|$  and  $|S_{32}|$  curves are normalized by the same factor to fix the maximum of  $|S_{32}|$  at 0 dB. g–i, Frequency line cuts from panels d and e, shown for three representative input power levels.

terference with the parasitic transmission. In contrast, for the longer edge path (port 1 to 3), the same coupling occurs; however, the increased path length induces an out-of-phase interaction with the parasitic transmission. This phase mismatch results in destructive interference between the plasmonic and parasitic paths, thereby reducing overall transmission. As the input intensity increases, a transmission dip gradually emerges, reaching a minimum at P = -119 dBm (Figs. 3 h and i). In addition to the broad-band transmission reduction from port 1 to 3, this dip provides exceptionally high isolation, exceeding 50 dB within a bandwidth of approximately 5 MHz.

#### C. Simulation

We now turn to understanding the origin of the sharp transmission dip and the associated negative group delay. This behavior stems from the non-reciprocal interaction between a pair of LC resonators and a chiral EMP resonator. The system is modeled by a minimal non-Hermitian Hamiltonian, assuming ideal non-reciprocity [15, 25, 26]:

$$H_{\text{eff}}/\hbar = \begin{pmatrix} \nu_a - i\kappa_a & g & 0 & 0 \\ 0 & \nu_{m_1} - i\kappa_{m_1} & g & 0 \\ 0 & 0 & \nu_b - i\kappa_b & g \\ g & 0 & 0 & \nu_{m_2} - i\kappa_{m_2} \end{pmatrix}$$
(1)

where  $\kappa_a$  and  $\kappa_b$  are the decay rates of the input and output LC resonators, respectively.  $\kappa_{m1}$  and  $\kappa_{m2}$  are the decay rates of the EMP resonators along different propagation paths, as illustrated in Fig. 1b.  $\nu_{a,b,m_1,m_2} = \omega - \omega_{a,b,m_1,m_2}$  is the frequency detuning of the electromagnetic field with respect to the LC and EMP resonance at frequency  $\omega_{a,b}$  and  $\omega_{m_1,m_2}$ , respectively. g denotes the coupling strength between the resonators. Given the almost identical resonance frequencies of the input and output LC resonators (Fig. 5b), we set  $\omega_a = \omega_b = \omega_0$  and  $\kappa_a = \kappa_b = \kappa_0$ . In the EMP resonator, asymmetric coupling emerges due to its chiral nature, leading to differences in propagation time and loss for the  $m_1$  and  $m_2$  modes depending on the path length and input microwave power. By applying coupled mode theory, the transmission can be expressed as:

$$t(\omega) = -\frac{\sqrt{2}\kappa_0 \alpha_m g^2}{\alpha_0^2 \alpha_m^2 - g^4} \tag{2}$$

where  $\alpha_0 \equiv -i\omega + i\omega_0 + \kappa_0$  characterizes the LC resonator and  $\alpha_m \equiv -i\omega + i\omega_m + \kappa_m$ characterizes the EMP resonator. Given that the path length of mode  $m_1$  is approximately twice that of  $m_2$ , we set  $\alpha_{m_1} = 2\alpha_{m_2}$  and  $\alpha_m = \sqrt{2}\alpha_{m_2}$  near the exceptional point.

We find that the measured transmission spectra are qualitatively in agreement with the theoretical model, indicating that the circulation mechanism is governed by asymmetric coupling between the LC resonator and the EMP mode (Figs. 4 a and b). At low excitation power, the measured transmission closely matches the model, with fitted parameters:  $g/2\pi =$ 

Figure 4. Comparison of data and simulation. a, b, Close-up views of the experimental (a) and simulated (b) spectral responses as a function of frequency and input power. The white (orange) dashed line indicates the input power corresponding to the measurements shown in c, d. c, d, Measured  $|S_{31}|$  magnitude (blue dots) as functions of frequency at excitation powers of P = -134 and -119 dBm, respectively. The solid red curves represent fits from the theoretical model in Eq. 2 . e, Measured phase difference between  $S_{31}$  and  $S_{32}$  at an excitation power of approximately  $P \sim -113$  dBm. e, Calculated phase response based on Eq. 2, using parameters extracted from the fit shown in d.

4.9 MHz,  $\kappa_0/2\pi = 0.9$  MHz, and  $\kappa_m/2\pi = 1.3$  MHz (Fig. 4 c). As the input power increases, the fitted coupling strength g rises to 6.1 MHz, while  $\kappa_0/2\pi$  and  $\kappa_m/2\pi$  increase to 2.0 and 2.7 MHz, respectively, at the point of maximum isolation (Fig. 4 d).

This simple model also captures the phase behavior observed in the experimental data, especially near the exceptional point, as shown in Figs. 4 e and f. In this case, the phase response of  $S_{31}$  is corrected by subtracting the phase of  $S_{32}$  to eliminate the line phase shift, allowing for a direct comparison with the theoretical result. The residual mismatch between experiment and theory at higher power is attributed to the power-dependent plasmon damping and coupling effects that lie outside the minimal model.

# III. CONCLUSION

In this work, we demonstrated a novel circulation mechanism in a topological circulator comprising a QAH edge magnetoplasmonic resonator coupled to LC resonators. Within an input power range of -150 to -120 dBm, the circulator maintains a relatively stable bandwidth and passband center frequency, indicating robust performance under low-power conditions. This power independence suggests the device is well-suited for integration into superconducting quantum information science platforms and high-energy physics experiments. If fully harnessed, this mechanism could facilitate the realization of a topological circulator with near-unitary forward transmission and exceptionally high isolation in the reverse direction. In conclusion, our results highlight the significant potential of Chiral plasmons to provide enhanced control over signal transmission and isolation across a wide dynamic range.

## Appendix A: Experimental configuration and device fabrication

The transmission of the circulator is probed by measuring the  $S_{21}$  transmission parameters for various powers. The experimental configuration is summarized in Fig. 1. The  $S_{21}$ measurements were performed on two ports of the circulator with an RF switch located at

Figure 5. Transmission spectra of the device without and with the inductors measured at room temperature. a, Complete six-way transmission response of the circulator without inductors at room temperature, with S-parameter measurements showing full reciprocity and a frequency response resulting from the LC impedance-matching circuits. b, Directionally measured magnitude of  $S_{ij}$  for the same circulator with the mounted inductors.

room temperature. The input microwave signals transmit through coax cables with a 20 dB attenuator at room temperature (not shown in Fig. 1a) and a 20 dB attenuator at 4 K. The total attenuation from the vector network analyzer down to the sample is about -64 dB. The power values expressed in decibels in this letter represent the estimated power at the input port of the circulator. The circulator output goes through a cryogenic isolator at the still stage and is amplified by a HEMT amplifier (LNF-LNC0.3-14A, Low Noise Factory) with a noise temperature of  $\sim 2$  K at the 4 K stage. At room temperature, the transmission signal is further amplified by a low-noise room temperature amplifier with a total gain of 20 dB (ZX60-4016E-S+, Mini-Circuits).

The 6 quintuple layers of  $Cr_{0.12}(Bi_{0.26}Sb_{0.62})_2Te_3$  thin films were grown using ultrahigh vacuum molecular beam epitaxy. Epi-ready semi-insulating ( $\rho > 10^6 \ \Omega \ cm$ ) GaAs (111) B substrates were pre-annealed in the chamber at up to 600 °C under Te-rich environment. During the co-evaporated growth, high-purity Bi (99.9999%), Te (99.9999%), Cr (99.99%) were evaporated from Knudsen effusion cells while Sb (99.999%) was evaporated from a cracker cell. Upon material growth, the circulator devices were fabricated via standard photolithography. The mesa disk was first patterned by photolithography and then etched by  $CF_4/Ar$  using reactive ion etching. The coplanar waveguides and ground planes were patterned by photolithography, and 10 nm of Ti and 100 nm of Au were deposited using electron beam deposition, followed by a liftoff process. Appendix B: Room temperature device characterization

Figure 6. Transmission spectra from port 1 to 3 at various input powers. The transmission dip shows a power-dependent frequency shift.

The circulator sample was initially characterized without a matching inductor and its impedance was expected to be on the order of the Hall resistance,  $\rho_{xy} = 25 \text{ k}\Omega$ . Since the impedance of the measurement circuit was 50  $\Omega$ , the lack of a matching circuit at the input results in a power reflection of approximately 99% at the input port of the circulator. As a control, we first measured all microwave S parameters before mounting the inductors, observing that all ports are equivalent with a transmission magnitude approximately -50dB at 530 MHz, as shown in Fig. 5b.

We then implemented a matching network at the input ports of the circulator by utilizing 3 lumped element 180 nH inductors in series (Fig. 1). The inductors coupled with the effective capacitance of the circuit serve as an impedance matching network for the 50  $\Omega$ coaxial lines and the high impedance of the circulator (Fig. 1b). Physically, the matching process utilizes the resonance created by the inductors and the effective stray capacitance of the circuit. The resonance is made coincident with the circulator edge magnetoplasmonic resonance frequency, effectively increasing the energy coupled into the circulator. Increasing the energy coupled into the circuit increases the signal-to-noise ratio. In practice, better coupling improves the insertion loss associated with reflections arising from impedance mis-

Figure 7. Phase of  $S_{31}$  is offset by phase of  $S_{32}$  at various input powers. The measured phase difference of  $S_{31}$  and  $S_{32}$  at an input power of P = -119 dBm is shown in (a), while the phase difference at different input powers is presented in **b**.

match. The appropriate inductor value was determined by testing different inductors on a similar sample and collecting transmission measurements at room temperature. Figure 5b shows the six-way transmission spectra, which illustrate reciprocal transport with an LC resonant frequency of f = 643 MHz, an amplification magnitude of 47 dB, and a quality factor of Q = 232.

# Appendix C: Power dependent transmission measurements for $S_{31}$

Figure 6 shows the  $S_{31}$  magnitude plotted for various powers, uncovering interesting nonlinear features which hint at the underlying physics of the anomalous Hall circulator. Signal incoming on the port 1 exhibits a power-dependent shift in both frequency and bandwidth, while transmission excited from port 2 does not exhibit a power dependence. The observed power dependence of the dip frequency can be directly attributed to the dynamics of the topological state. At sufficiently low powers, i.e., below -130 dBm, the topological edge state is separated from the bulk state and dissipationless chiral edge magnetoplasmon currents excite plasmonic modes,  $\lambda \sim 2\pi R$ . As the power increases, microwave photon-induced hopping occurs in the charge puddles of the bulk, which is capacitively coupled to the edge states, and dissipation begins to set in. At sufficiently high powers, the shift in frequency can be associated with an enhanced edge capacitance of the QAH material. This aligns with prior experimental findings in circulators utilizing anomalous Hall materials.

The phase difference between  $S_{31}$  and  $S_{32}$  at different excitation powers is illustrated in Fig. 7. At the maximum  $S_{31}$  transmission dip (P = -119 dBm), a 180°-phase shift is observed (Fig. 7a). The slope of phase change decreases when P exceeds -119 dBm (Fig. 7b).

Figure 8 shows the non-reciprocity  $|S_{32}| - |S_{31}|$ , resonant frequency shift, and the 3 dB bandwidth as a function of input power. Note, for input powers in the range of -145 to -125 dBm the circulator's bandwidth and passband center frequency are relatively power independent suggesting the circulator can exhibit a stable regime in power ranges that are relevant to superconducting quantum information science platforms and high-energy physics experiments.

Figure 8. Parameters associated with the absorption spectra as a function of input power. The non-reciprocity, defined as the difference between  $|S_{32}|$  and  $|S_{31}|$ , along with the frequency dip in  $|S_{31}|$  and the 3 dB bandwidth of the absorption spectra, are plotted as functions of input power.

#### Appendix D: Insertion loss characterization

The insertion loss of the circulator was measured in a different Bluefors dilution refrigerator after the sample had been stored for more than two years at ambient temperature in a low-vacuum desiccator. The characterization diagram is shown in Fig 9. The circulator was cooled to below 30 mK. A network analyzer was used to perform  $S_{21}$  transmission measurements through the system. To determine the insertion loss of the circulator, a transmission measurement was made through the transmission port  $(I_1)$  and the proportion of power transmitted through the receiver was measured at the output  $(O_1)$ . Two cryogenic switches (Radial R585433210) enabled swapping between the circulator ports and a short cable. In addition, a second transmission line  $(I_2)$  was used to measure the isolation of the circulator. On the output line  $(O_1)$ , the signal was amplified by a HEMT amplifier mounted to the 4 K stage, followed by a room temperature amplifier. An isolator before the HEMT amplifier was used to reduce standing waves within the receiver. Broadband transmission measurements were made of both the  $S_{32}$  and  $S_{31}$  of the circulator. At cryogenic temperatures, there is a  $\sim 2$  dB difference in transmission between input lines  $I_1$  and  $I_2$ .

Figure 9. Experimental setup for insertion loss measurements. The circulator is cooled to below 30 mK. A network analyzer is used to measure transmission through the receiver and two RF switches enable bypassing the circulator. Measurement of transmission with and without the circulator enable a direct measurement of the insertion loss of the circulator.

To determine the insertion loss of the circulator, transmission measurements were performed with the circulator both in the receiver circuit and bypassed, while applying a range of input powers. Any additional transmission losses observed when the circulator was switched

Figure 10. Insertion loss of the circulator at cryogenic temperature. a, Transmission of the circulator and the short bipass cable at the VNA power of  $P_{VNA} = -85$  dBm. b, An insertion loss of 5.9 dB is observed at the transmission peak of  $|S_{31}|$  with an isolation of ~ 20 dB.

in were attributed to its insertion loss. As shown in Fig. 10, the insertion loss of the circulator was found to be approximately  $5.9 \pm 2$  dB with an isolation of ~ 20 dB in the low power regime.
